

ESS 411/511 Geophysical Continuum Mechanics Class #15

Highlights from Class #14

– Alysa Fintel

Today's highlights on Wednesday

– Jensen DeGrande

Our text doesn't cover our next topics very thoroughly, so we will use a few other sources, which are posted on the class web site under READING & NOTES. <https://courses.washington.edu/ess511/NOTES/notes.shtml>

- Stein and Wyss session 5.7.2
- Stein and Wyss session 5.7.3/4
- Raymond notes on failure

Also see slides about upcoming topics

- Failure and Mohr's circles – slides

ESS 411/511 Geophysical Continuum Mechanics

Broad Outline for the Quarter

- Continuum mechanics in 1-D
- 1-D models with springs, dashpots, sliding blocks
- Attenuation
- Mathematical tools – vectors, tensors, coordinate changes
- Stress – principal values, Mohr's circles for 3-D stress
- Coulomb failure, pore pressure, crustal strength
- Measuring stress in the Earth
- Strain – Finite strain; infinitesimal strains
- Moments – lithosphere bending; Earthquake moment magnitude
- Conservation laws
- Constitutive relations for elastic and viscous materials
- Elastic waves; kinematic waves

Warm-up questions – (break-out)

Explain what's going on in each case.

(f)

$$p = -\sigma_{ii}/3$$

- What is p ?
- Why the minus sign?

Warm-up II

Greatest shear stress is on planes marked with normal vectors n_i at 45° to σ_{III} . But failure actually happens on planes marked – – – at an angle $\theta > 45^\circ$ between n_i and σ_{III}

Why is failure **not** on the plane with maximum shear stress?

All surfaces are roughs at some scale. Relate this failure angle to how one rough surface slides over another rough surface.

Failure planes – – – are defined by their normal vectors n_i .

Why are there 2 conjugate failure planes?

Relate this to the Mohr's circle.

Planes

Class-prep questions for today (break-out)

Failure of materials

Last class, we looked at frictional sliding on pre-existing fractures or faults with a coefficient of friction μ .

- What physical characteristics of a surface cause friction?

Now we are going to actually break new rocks.

Mohr–Coulomb failure

$$\sigma_S = \tau_0 - n \sigma_N$$

n = **coefficient of internal friction** for fracture on a new fault surface

τ_0 = cohesion of the material

- Explain what you think n and τ_0 might mean in terms of micro-scale processes at the micro-crack, crystalline, or lattice scales.
- Why do you think the failure envelope is rounded off at the right? Think about the sign of σ_N and the processes that might contribute to internal friction.

Style of Failure under Various Normal Stresses σ_N

The figure is a graph of shear stress (τ) versus normal stress (σ). The vertical axis is labeled σ_s at the top. The horizontal axis is labeled σ at the right. A dashed vertical line marks the origin, with T_0 indicated on the horizontal axis. A horizontal dashed line is labeled "Yield stress". A solid curve, labeled "Parabolic fracture envelope", starts at the origin and curves upwards. A solid straight line, labeled "Coulomb fracture criterion", starts at a positive value on the vertical axis and slopes upwards. A vertical line marks the "Brittle-ductile transition". To the right of this line, a horizontal line is labeled "Von Mises ductile failure criterion". The graph is divided into five regions labeled A, B, C, D, and E. Each region contains a Mohr circle diagram and a photograph of a rock specimen. Region A is at low stress, showing a small Mohr circle and a specimen with a vertical crack. Region B is at low to moderate stress, showing a larger Mohr circle and a specimen with a diagonal crack. Region C is at moderate stress, showing a larger Mohr circle and a specimen with a diagonal crack. Region D is at high stress, showing a larger Mohr circle and a specimen with a diagonal crack. Region E is at very high stress, showing a larger Mohr circle and a specimen with a diagonal crack. The Coulomb criterion is shown as a straight line, while the parabolic envelope is a curve that eventually merges with the Coulomb line. The Von Mises criterion is a vertical line at high stress. The transition from brittle to ductile behavior occurs between C and D.

- Describe in words what is happening in this generalization of the failure envelopes that we have discussed in class.
- In a sentence or two for each, describe characteristics of the failure mode in each of the 5 stress regimes *A*, *B*, *C*, *D*, and *E*. The regime names, the angles of the failure planes, and the visual states of the samples after the experiments ended may be helpful.

4 Conventions in Stress Polarity

Engineering/Mathematical convention:

Criterion 1: Positive σ_{ii} * signifies extension

Criterion 2: Order $\sigma_I > \sigma_{II} > \sigma_{III}$ (Mase & Mase)

or

$$\sigma_I < \sigma_{II} < \sigma_{III} \text{ (Stein \& Wyss)}$$

Geologic/Tectonic/Rock Mechanics convention:

Criterion 1: Positive σ_{ii} * signifies compression

(not a tensor!! Why not?)

Criterion 2: Order $\sigma_I > \sigma_{II} > \sigma_{III}$ (Twiss & Moores)

or

$$\sigma_I < \sigma_{II} < \sigma_{III} \text{ (?)}$$

* No sum implied

Sliding friction

$\sigma_s = -\mu \sigma_N$ μ is ***coefficient of friction*** for sliding on a pre-existing break

Differential stress

$$\sigma_I - \sigma_{III}$$

Differential stress is essential in order to have failure

How could we change the stress state in order to cause failure?

- Hold σ_I make σ_{III} more negative (squeeze harder in x_3)
- Hold σ_{III} , make σ_I less negative (don't squeeze as hard in x_1)

Types of faults

The Earth's surface is traction-free, so one of the principal directions is generally vertical

What are the orientations of the principal axes of stress \hat{e}_1^* , \hat{e}_2^* , \hat{e}_3^* in each case?

Mohr-Coulomb Fracture

$\sigma_S = \tau_0 - \eta \sigma_N$ η is ***coefficient of internal friction*** for fracture on a new fault surface

τ_0 is cohesion of the material in absence of any confining stress σ_N

Failure in shear

- Why is failure is not on the plane with maximum shear stress?
- Why are there 2 conjugate failure planes?

Mohr-Coulomb Fracture

Now we are actually breaking rock ...

$\sigma_S = \tau_0 - n \sigma_N$ n is **coefficient of internal friction** for fracture on a new fault surface
 τ_0 is cohesion of the material in absence of any confining stress σ_N

Figure 5.7-10: Relation between shear stress and normal stress for frictional sliding.

Lab experiments show a linear relation between the maximum shear stress that rocks can support at any given normal stress. This is called Byerlee’s Law.

$$\begin{aligned}\tau &\approx -.85\bar{\sigma} & \bar{\sigma} < 200 \text{ MPa} \\ \tau &\approx 50 - .6\bar{\sigma} & \bar{\sigma} > 200 \text{ MPa.}\end{aligned}$$

Coulomb stress

- Notion of friction:
 - More shear stress τ needed to overcome increase in normal stress σ and cause fault to slip – Byerlee's law is an example
- Coulomb stress
 - $\sigma_s = \tau - \mu (\sigma_N - p)$
 - where μ is intrinsic coefficient of friction, p is pore pressure (**not** the mean stress $p = -\sigma_{ii}/3$, need to be careful of context)
- Basis is that real area of contact (much smaller than apparent area) is controlled by normal stress
 - deformation of asperities in response to normal stress
 - harder to over-ride asperities at higher normal stress

Figure 5.7-10: Relation between shear stress and normal stress for frictional sliding.

Byerlee's law

$$\begin{aligned} \tau &\approx -.85\bar{\sigma} & \bar{\sigma} < 200 \text{ MPa} \\ \tau &\approx 50 - .6\bar{\sigma} & \bar{\sigma} > 200 \text{ MPa.} \end{aligned}$$
